# 17 Abstract

18 Microsatellite are powerful markers for empirical population genetics, but may be 19 affected by amplification problems like stuttering that produces heterozygote deficits 20 between alleles with one repeat difference. In this paper, we present a simple procedure 21 that aims at detecting stuttering for each locus overall subsamples and only requires the 22 use of a spreadsheet interactive application on any operating system. We compare the 23 performances of this procedure with the one of MicroChecker on simulations of dioecious 24 pangamic populations, monoecious selfing populations and clonal populations with or 25 without stuttering, and on real data of vectors and parasites. We also propose a cure for 26 loci affected and compare the results with those expected without stuttering. In sexual 27 populations (dioecious or selfers), the new procedure appeared more than three times 28 more efficient than MicroChecker, Cure was able to restore Wright's Fis of stuttered data to the expected value, and particularly so in selfing simulations. In clones, lack of segregation 29 30 artificially increased false stuttering detection, and only highly significant stuttering tests 31 and loci strongly deviating from others, could be usefully cured, in which case Fis estimate 32 could be much improved. In doubt, and whenever possible, removal of affected and not 33 curable loci may help to shift population genetics parameter estimates towards more 34 reliable values.

Supprimé: may

Supprimé: Cures are kept only if parameter estimates are improved as well as the behavior of their variation in relation to other factors as number of missing data (null alleles) or specific criteria for clonal populations.

## 54 Introduction

Despite the recent democratization of NGS based techniques, microsatellite loci are 55 still very useful markers, in particular for empirical population genetics of non-model and 56 57 small organisms, as many parasites and/or their vectors, which are difficult (or impossible) 58 to study with direct methods as direct observation (as for birds) or as mark-release-59 recapture approaches. Sequencing and single nucleotide polymorphism markers (SNPs) 60 still represent expensive alternatives in time, money and expertise, which lies beyond the 61 reach of many laboratories and most of the time at the expense of sample sizes. Three 62 decades ago, microsatellite markers were presented as the most powerful genetic markers 63 (Jarne & Lagoda, 1996). However, researchers began to detect the different problems that 64 can arise and developed different kinds of cures. The last kind of detection tools and cures only arose very recently (Wang et al., 2012; De Meeûs, 2018; Manangwa et al., 2019; De 65 66 Meeûs et al., 2021).

67 Stuttering is the result of the Tag polymerase slippage during the PCR amplification 68 of the targeted DNA strand. This generates several PCR products that differ from each 69 other by one repeat and can cause difficulties when discriminating between fake and true 70 homozygotes, such as heterozygous individuals for dinucleotide microsatellite allele 71 sequences with a single repeat difference (De Meeûs et al., 2021). Stuttering produces 72 heterozygote deficits as compared to Castle-Weinberg (CW) expected genotypic 73 proportions (Castle, 1903; Weinberg, 1908), also known as Hardy-Weinberg (HW) 74 expectations (please have a glance at (De Meeûs et al., 2021) for an explanation why we 75 prefer using CW instead of HW). This phenomenon is locus specific and the deviation 76 produced, as measured by wright's Fis (Wright, 1965), proportional to the intensity with 77 which each locus is affected.

Today, and to our knowledge, the only procedure to detect stuttering is the one
used in MicroChecker (Van Oosterhout et al., 2004). Though it works well enough, it only
studies each locus one by one, which is fine because stuttering presence and intensity are
expected to be locus specific. Nonetheless, MicroChecker tests for stuttering in each

82 subsample separately, though a global test might be more powerful, Furthermore,

83 MicroChecker was developed under Microsoft® Windows in 2003 (Windows XP), and it

84 begins to display incompatibility issues with most current systems, A simple alternative,

which can detect and test for the presence of stuttering at each locus overall subsampleson any platform kind would thus be welcome and timely.

87 In this paper, we present a very simple procedure that only requires the use of a
88 spreadsheet interactive computer application such as Apache® OpenOffice Calc or

### Supprimé: s

Supprimé: , especially so for non-model organisms

**Commenté [FH2]:** reference to Guichoux et al. 2011 Balloux, F., Lehmann, L., & Meeûs, T. de. (2003). The Population Genetics of Clonal and Partially Clonal Diploids. *Genetics*, 164(4), 1635–1644.

Supprimé: It is probable that SNPs will experience the same fate. Null alleles are known to exist in SNP (Vignal et al., 2002) and these markers may display frequent allelic dropouts (Bayerl et al., 2018). Ascertainment bias represent a very serious issue for non-model organisms (Garvin et al., 2010). The number of SNPs needed is at least 200 to compete with microsatellite information (Séré et al., 2017), which raises new problems regarding some testing procedures as neutrality tests or linkage disequilibrium (LD) tests. LD tests are classically undertaken between pairs of loci. Given the very low power of individual LD tests, which is aggravated by false discovery rate (FDR) procedures, such as Benjamini and Yekutieli's (Benjamini & Yekutieli, 2001), required on nonindependent tests series, the number of genotyped individuals required to reach a reasonable power might often look prohibitive for most laboratories. This is particularly true for parasitic organisms and their vectors as Ixodes scapularis the vector of Lyme disease in North America (De Meeûs et al., 2021), and even more critical regarding the actors of neglected tropical diseases, among which fasciolasis and African trypanosomiasis cause much economic and health issues and represent significant constraint on development (Solano et al., 2010; Hunter, 2014; Correa et al., 2017)

**Commenté [FH3]:** It could have been interesting to review the different pitfalls, and highlight that stuttering is still an issue. Other biais can be corrected, e.g. null alleles (Chapuis et al. 2007) Chapuis, M.-P., & Estoup, A. (2007). Microsatellite null alleles and estimation of population differentiation. *Molecular Biology and Evolution*, 24(3), 621–631. doi: 10.1093/molbev/ms1191

#### Supprimé: the

Supprimé: and robust Supprimé: .

#### Supprime

Supprimé: In the most recent version (Windows 10) running the setup program can be tricky. On some computers, the setup program stops at some percent of the process and the user must end it and run again the setup program as many times as necessary (e.g. six times). We may fear that next versions of Windows will be completely incompatible with this program. For other operating systems, MicroChecker requires some specific emulators to work

130 Microsoft® Excel. We compare the performances of this new procedure with the one 131 implemented in MicroCheker on simulated data without (null hypothesis) or with 132 (alternative hypothesis) stuttering, in dioecious populations of various sizes with random 133 mating, hermaphrodites with selfing or clonal populations. We also checked how the cure 134 proposed in De Meeûs et al. (2021) of loci with stuttering signature restore the values 135 expected for some parameters. We finally reanalyzed four real data sets on vectors and/or 136 their parasite: the tick Ixodes scapularis in North America (De Meeûs et al., 2021); 137 Glossina palpalis palpalis, vector of African trypnosomiasis in Côte d'Ivoire (Berté et al., 138 2019); the snail Galba truncatula and the fluke it transmits, Fasciola hepatica in France 139 (Correa et al., 2017); and Trypanosoma brucei gambiense, the agent of sleeping sickness in Guinea and Côte d'Ivoire (Koffi et al., 2009). On these datasets, we checked if more loci 140 141 with stuttering could be diagnosed, cured the loci with suspicion of stuttering, following the 142 technique proposed recently (De Meeûs et al., 2021) to verify if some conclusions could be 143 changed. 144 145 **Material and Methods** 146 Simulations 147 Simulations were undertaken with EASYPOP (v. 2.0.1) (Balloux, 2001). We 148 simulated random mating dioecious populations (pangamy), like what probably occurs in 149 the wild for ticks (De Meeûs et al., 2021), Nematocera flies (Prudhomme et al., 2020), 150 Hemipteran bugs (Gomez-Palacio et al., 2013), or tsetse flies (Berté et al., 2019). We also 151 simulated selfing monoecious populations, as flukes and water snails (Correa et al., 2017). 152 The total size of populations was  $N_{\rm T}=10,000$  individuals subdivided into either n=100153 subpopulations of N=100 individuals, or n=500 and N=20, with an even sex ratio (dioecy) 154 or with selfing rate s=0.3 (monoecy). The model of migration followed an Island model with 155 migration rate m=0.01. We simulated 20 independent loci with a mutation rate of u=0.0001that followed a mixed model with 70% of mutations following a stepwise mutation model 156 157 (SMM) and 30% following a KAM model. The maximum possible number of alleles was 158 K=20. Each simulation started with maximum variability and was run for 10,000 159 generations. At the end of each simulation, 20 individuals (10 males and 10 females in 160 dioecious populations), when *N*≥20, were randomly sampled in 10 subpopulations. As can

For each individual carrying one of these alleles as the second allele, if different by a single repeat from the first allele, the second allele was recoded as identical to the first one. Let us assume that the first two alleles separated by a single repeat were, for instance, allele 5 and 6 for the first locus (Locus1). If allele 5 was in cell B2 and allele 6 in cell C2 in the spreadsheet, the command for generating stuttering in a cell from a free zone (e.g. the first free column after the last column of the data) would be: =B2, for the first allele (no change), and =IF(ABS(B2-C2)=1,IF(OR(B2=5,B2=6),B2,C2),C2), for the second allele of that locus. This way, individuals 4/5, 5/6, or 6/7 are recoded as homozygotes for the first allele.	Supprimé: identitiy         Commenté [FH4]: output files from EasyPop , no ?         Supprimé: , which         Commenté [FH5]: add a sentence here : For mimicking stuttering we proceeded as follow :         Supprimé: in English or¶         =SI(ABS(B2-C2)=1;SI(OU(B2=5;B2=6);B2;C2);C2) in French

204	A template, using the first simulation, can be found in the supplementary material
205	files as the spreadsheet file "TestStutterDioecious-n1000N100-1-10%Stuttering.xlsx".
206	Because of drift, some loci in some subsamples did not display allele with one
207	repeat difference. Such manipulation thus generated data with 0% to 100% of alleles
208	displaying stuttering for all of the 20 loci, but with various intensity from one locus to the
209	other, and from one subsample to the other, as expected in real situations. This also
210	allowed checking the kind of variance stuttering can generate on parameter estimates (see
211	below).
212	

## 213 Detection of stuttering and testing with MicroChecker

All datasets (raw and with stuttering) were analyzed with MicroChecker with 10,000

randomizations. All loci were considered as mononucleotidic, as simulated by Easypop.

216 Stuttering was detected when the observed heterozygosity for alleles with one repeat

217 difference was below the 95% confidence interval (95%CI) for random mating expectation.

218 This was observed from the graphic outputs of MicroChecker (Figure 1).

220	Figure 1: Examples of significant stuttering tests using MicroChecker graphic outputs.
221	Black crosses represent the number of observed genotype of a given class and red
222	diamonds stand for the corresponding values expected under the null hypothesis
223	(random mating). The abscissa are the different genotypic classes in terms of size
224	differences between the two alleles within an individual (e.g. 0 stands for
225	homozygous genotypes). 1-A: an example with a significant homozygous excess
226	and a significant deficit of heterozygotes with one repeat size difference between
227	the two alleles. 1-B: an example where only the deficit of heterozygotes with one
228	repeat size difference between the two alleles was significant. In the present paper,
229	both situations are considered significant while only the first one is for
230	MicroChecker,

234	For each locus, we summed the number of times MicroChecker found a significant		
235	heterozygote deficit probably due to stuttering over the 10 subsamples. We compared this		
236	quantity with the expected 5% under the null hypothesis with a one sided exact binomial		
237	test with R (R-Core-Team, 2020) (command "binom.test"). The alternative hypothesis was		
238	that there are more than 5% significant tests. This test was repeated 20 times across the		
239	different loci. To take into account this repetition of independent tests, we used the		
240	Benjamini and Hochberg's (BH) false discovery rate (FDR) procedure (Benjamini &		
241	Hochberg, 1995) with R (R-Core-Team, 2020) (command "p.adjust") to identify which tests		
242	are really significant (see (De Meeûs et al., 2009)).		
243			
244	Alternative method to detect and test for stuttering		
245	We needed to compute the expected frequency of individuals heterozygous for two		
246	alleles with one repeat difference, for each locus over all subsamples. All allele		
247	frequencies outputted and sorted by Fstat were copied in a spreadsheet. Let us assume,		
248	for instance, that subsample size was in cell B3, that the size of the smallest allele of the		
249	first locus of the first subsample was in cell A4 and its frequency in cell B4, and allele size		
250	and allele frequency of the second allele was in cells A5 and B5 respectively. Then the		
251	expected frequency of individuals heterozygous for two alleles with one repeat difference		
252	was obtained by typing the following command in, for instance, cell C4:		
253	=IF(ABS(\$A4-\$A5)=1,2*B4*B5*B\$3,0),		Supprimé: in English and¶ =SI(ABS(\$A4-\$A5)=1:2*B4*B5*B\$3:0) in French
254	As can be seen, for two successive alleles with more than one repeat difference,	C	
255	this expected frequency was set to 0. Please, note that for a dinucleotidic locus the		
256	difference in size must be two (e.g. ABS(\$A4-\$A5)=2). For imperfect dinucleotidic loci, the		
257	conditional command would be of the form		
258	=IF(OR(ABS(\$A4-\$A5)=1, ABS(\$A4-\$A5)=2),2*B4*B5*B\$3,0), to include both the cases of		
259	one base difference, which may also generate stuttering, and of two bases (one repeat)		
260	difference,		<b>Supprimé:</b> in English and¶ =SI(OU(ABS(\$A4-\$A5)=1: ABS(\$A4-
261	Now, if the penultimate allele is on line 10 of the spreadsheet, the sum of all	l	\$A5)=2);2*B4*B5*B\$3;0) in French
262	expected heterozygotes with one repeat difference for the concerned locus and subsample		
263	was obtained by typing the following command in, for instance, cell C12:		
264	=SUM(C4:C10),		Supprimé: in English and¶ =SOMME(C4:C10) in French
265	Finally, if this sum for the last subsample is in column U, then, the total number of		
266	expected heterozygotes with one repeat difference across all subsamples for that locus		
267	was obtained with:	C	e a la facto de Francisko de let
268	=SUM(C12:U12),		Supprime: In English and¶ =SOMME(C12:U12) in French
	8		

279this, we copied the raw data (one allele per column) in a spreadsheet. Let us assume that the first allele of the first locus of the first individual was in cell B2 and the last allele of the last locus of the first individual was in cell AO2. In cell AO2 we typed: ====================================	278	Then, we needed to compute the observed frequency of such heterozygotes. For	
the first allele of the first locus of the first individual was in cell B2 and the last allele of the last locus of the first individual was in cell AO2. In cell AO2 we typed: =IF(ABS(B2-C2)=1,10). Please, note again that for dinucleotidic loci, the difference in size would be two, and it should be one and two for imperfect dinucleotidic loci. We then copied this command in all remaining cells corresponding to the rest of the dataset. In the cell AO202 (below the last line of the data), to compute the total of observed heterozygous individuals for alleles with one repeat difference, we typed: =SUM(AO2:AO201), A template, for the first simulation, is available in the spreadsheet file TestStutterDioeciousNoStutter-n1000N100-1-FstatRes.xts.' We then compared the observed and expected frequencies with a one sided exact binomial test with R, the alternative hypothesis being "there are less heterozygote observed with 1 repeat difference than expected". This provided 20 independent p-values that we corrected for False Discovery Rate with the Benjamini and Hochberg's procedure. With selfing, natural homozygosity increase may artificially enhance stuttering detection. Nevertheless, since there is no easy way to estimate precisely the selfing rate in case of stuttering, we did not adapt stuttering detection. For clonal propagation, full clonality exhibits specific signature regarding genetic diversity, Fis and linkage disequilibrium (De Meeûs & Balloux, 2004; 2005; De Meeûs et al., 2006; Séré et al., 2014). Nevertheless, as shown by the simulations we undertook, the absence of segregation makes it impossible to predict the expected frequency of specific heterozygous classes. This led us to entirely modify stuttering detection in that case. Knowing that the expected total heterozygosity should be $H=(K-1)/K$ (K is the total number of possible alleles). The quantity K is never known, so we considered the total number of alleles observed K <sub>0</sub> , as an underestimate, with $H=(K-1)/K$ . Some heterozygote	279	this, we copied the raw data (one allele per column) in a spreadsheet. Let us assume that	
281last locus of the first individual was in cell AO2. 316	We can see that this way the sum of all $H_{expij}$ indeed reaches $H'$ . For each locus,		
317	$H_{expij}$ was computed for each heterozygous class with one repeat difference within each		
318	subpopulation. We then summed all these expected frequencies over all heterozygote		
319	classes with one repeat difference and multiplied it by 20 (subsample size) to obtain the		
320	expected number of heterozygotes with one repeat difference for a given subsample. We		
321	then summed the results obtained across all the 10 subsamples to obtain the total number		
322	of expected heterozygotes with one repeat difference and compared it, for each locus, to		
323	the one observed in the simulation. Since $K_0 \leq K$ , these expectations may be under-		
324	estimates of the real expected frequencies. We might thus expect a deficiency in stuttering		
325	detection. Alternatively, since drift should favor particular heterozygous classes by chance,		
326	we also expect a total lack of other heterozygous classes, which may lead to strongly		
327	significant spurious stuttering signatures.	C	Commenté [FH7]: This looks like a stuttering wording
328		P	pattern (SSSS) ;-)
329	Estimation of Fixation indices and linkage disequilibrium	S	upprimé: estimation
330	Wright's F-statistics (Wright, 1965) estimated with Weir and Cockerham's estimators		
331	(Weir & Cockerham, 1984) were computed. $F_{\rm IS}$ measures inbreeding of individuals relative		
332	to inbreeding of their subpopulation and $F_{\text{ST}}$ measures inbreeding of subpopulations		
333	relative to the total inbreeding. We also computed the 95% confidence intervals of		
334	bootstrap over loci of these statistics. These were estimated and computed with Fstat		
335	2.9.4 (Goudet, 2003) updated from Fstat 1.2 (Goudet, 1995).		
336	Amplification problems can increase the variance of <i>F</i> -statistic estimation across		
337	loci, and this affects more the $F_{\rm IS}$ than the $F_{\rm ST}$ (De Meeûs, 2018). We used the jackknife		
338	over loci estimate of the standard error of $F_{IS}$ and $F_{ST}$ (StdrdErrFIS and StdrdErrFST) of		
339	Fstat to measure the effect of stuttering on parameter variation across loci. In particular, in		
340	case of null alleles, StdrdErrFIS is at least twice StdrdErrFST (De Meeûs, 2018). We thus		
341	measured the ratio R <sub>SE</sub> =StdrdErrFIS/StdrdErrFST.	S	Supprimé:
342	Linkage disequilibrium can be favored by allele miscoring (De Meeûs et al., 2021).		
343	We thus tested linkage disequilibrium between all pairs of loci with the G-based		
344	randomization test of Fstat over all subsamples because it is the most powerful for		
345	combining tests across subsamples (De Meeûs et al., 2009). The False Discovery Rate for		
346	dependent tests series was computed following Benjamini and Yekutieli procedure	S	Supprimé: (BY)
347	(Benjamini & Yekutieli, 2001) with R (command p.adjust).		
348			

#### 352 Statistical comparisons of method performances 353 Performance of tests were compared with the Fisher exact test with R-commander 354 package (Fox, 2005; Fox, 2007) for R. 355 We also undertook generalized linear mixed models with the package Ime4 (Bates 356 et al., 2015) of R to explain the number of times a test appeared significant. We used a 357 Poisson distribution with a log link. The models were of the form 358 NSig~n+N+Mating+Stuttering+Mating:Stuttering+(1|Rep) 359 where NSig was the number of loci that outputted a significant stuttering test or the 360 number of locus pairs that appeared in significant LD, n is the total number of 361 subpopulations, N was the size of subpopulations, Mating was the mating system (either 362 pangamic dioecy or Monoecy with 30% selfing), Stuttering was either 0 (no stuttering) or 10 (10% stuttering), ":" stood for interaction between two variables, and (1|Rep) was the 363 364 random effect of replicates. 365 366 Cured data sets 367 Stuttering correction was made for loci that appeared with a significant stuttering at 368 the BH level with the new method described in the present paper. We used the rules 369 described in (De Meeûs et al., 2021): for each incriminated locus, all alleles with one 370 repeat difference were pooled together. Each group of pooled alleles contained an allele 371 the frequency of which was at least 0.05. The main principle behind this rule is that rare 372 alleles should keep small weights in the data. Pooling rare alleles together may artificially 373 create a fairly frequent artificial allele, with a strong though artificial weight. Pooling rare 374 alleles with a reasonably frequent one is supposed to attenuate this problem. If no frequent 375 allele was available, then two solutions were chosen. If the sum of the frequencies of these 376 alleles remained below 0.05, these were not pooled, Otherwise, to minimize the impact 377 that these successive alleles may jointly have on the heterozygote deficit, and to avoid 378 pooling rare alleles together, they were pooled with the closest allele with frequency above 379 or equal to 0.05, even if more than one repeats distant from the closest one. 380 In rare cases, all alleles were one repeat different. To prevent obtaining a 381 monomorphic locus in that case, we pooled alleles two by two, taking care of one of the 382 two alleles pooled displayed a frequency of at least 0.05. In case of uneven number of 383 alleles, the last allele was not left alone and pooled with the previous pair in allele size.

Cured data were reanalyzed and statistics compared with the results expected
under the null hypothesis (without stuttering). The efficiency of the correction was checked
for each locus in each replicate of each simulation. We retained only the corrected loci for

**Commenté [FH8]:** awkward sentence. Change to : Each group of pooled alleles contained one allele with a frequency of at least 0.05%.

Supprimé: ,	
Supprimé: i

which the correction produced a lower  $F_{IS}$  as compared to the value obtained with the uncured locus. The average  $F_{IS}$  and 95% bootstraps confidence intervals were thus computed on data sets with efficiently cured loci and uncured remaining loci. These values were compared to those obtained under the null hypothesis (no stuttering), and to expected value for Wright's  $F_{IS}$ ,  $F_{IS\_exp}$ . For pangamic dioecious populations we used equation 8 from Balloux (2004) (Balloux, 2004):  $F_{IS\_exp}$ =-1/(2*N*+1). For selfing populations, we used the classic  $F_{IS\_exp}$ =s/(2-s) (e.g. (De Meeûs et al., 2007) page 213).

### 399 Real data sets

398

400 Five data sets were reanalyzed: two regarding dioecious species, two regarding401 monoecious species and the last regarding a clonal species.

402 The first real data set reanalyzed was on the tick *Ixodes scapularis* the vector of
403 Lyme disease in western USA (De Meeûs et al., 2021). We used the data cured for short
404 <u>allele dominance (SAD)</u> as explained in the originator paper (De Meeûs et al., 2021) but
405 uncured for stuttering.

406 The second data set concerned the tsetse fly Glossina palpalis palpalis, an 407 important vector of sleeping sickness in Côte d'Ivoire (Berté et al., 2019), for which loci 408 X55-3 and pGp23 displaying uncured SAD and locus GPCAG, obviously under selection, 409 were removed. Because some loci were X-linked, only females were kept. Three 410 dinucleotidic loci (pGp20, pGp24, B3) displayed some discrepancies of allele sizes and 411 were marked as mononucleotidic for MicroChecker. For these loci, heterozygotes with 412 single and double nucleotide differences in size were checked for heterozygote deficit due 413 to stuttering.

The third and the fourth data sets concerned the highly selfing snail *Galba truncatula* and its parasite *Fasciola hepatica*, also monoecious but almost panmictic, in France (Correa et al., 2017). For both species, microsatellite profiles did not fit with the expected pure dinucleotidic motives and, again, stuttering was considered between alleles of 1 base and two bases differences in size.

419Finally, the clonal species studied was *Trypanosoma brucei gambiense* 1 in420Western African foci of sleeping sickness (Koffi et al., 2009), for which one locus421(Trbpa1/2), suspected of being under selection, was removed. For this data, we used a422derived version of Séré et al superimposition criterion (Séré et al., 2014). In pure clonal423populations, the expected value for *F*is is *F*is\_exp=-(1-*H*s)/*H*s, where *H*s is Nei's estimator of424local genetic diversity (measured within subsamples) (Nei & Chesser, 1983). This criterion425can only be used for sufficiently polymorphic loci with *H*s≥0.5. To express the goodness of

426	fit of observed $F_{IS}$ towards this value, we designed a superimposition index $S_{C}$ =  $F_{IS}$ -
427	$F_{s_{exp}}/max( F_{s} ,  F_{s_{exp}} )$ , where "max" means the maximum value of the two $F_{s's}$
428	absolute values.

## 430 Results and discussion

A synthetic view of simulation results, averages detail computations and test tables are available in the supplementary file S1 for sexual simulations and in the supplementary file S2 for clonal simulations.

# 434

### 435 Detection of stuttering in sexual populations

436 The results of these analyses are summarized in Table 1. Stuttering detection per 437 locus was weak in general, with 0‰ and 5‰ significant tests for MicroChecker and the 438 alternative methods, respectively, under the null hypothesis (H0: there is no stuttering) in 439 monoecious populations. For Microchecker, the total proportion of significant tests over all 440 loci and subsamples was 2‰ in that case. No test stayed significant after Benjamini and 441 Hochber, correction. In populations with 30% selfing, but still under H0 (i.e. no stuttering), 442 these proportions increased to 10% for the alternative method only. It dropped to 2.5‰ 443 after Benjamini and Hochberg correction. For MicroChecker over all loci and subsamples, 444 2% only appeared significant under H0 with selfing. With stuttering (H1), the number of 445 significant tests reached 7% and 24% in dioecious populations for MicroChecker and alternative methods respectively (5% and 17% respectively with Benjamini and Hochberg). 446 447 This reached 14% and 47% respectively with 30% selfing (10% and 38% respectively with 448 Benjamini and Hochberg). 449

**Commenté [FH10]:** yes but compared to the inital value, the increase is only 4.4 %. Not very different from the 4% in pangamic population.

Supprimé: seemed

509	I he ratio between standard errors of $F_{\rm IS}$ and $F_{\rm ST}$ was 1.04 on average under H0 in
510	95% CI=[0.95, 1.14] and reached 1.77 in 95%CI=[1.52, 2] with stuttering. It thus increased
511	slightly with stuttering but rarely reached $R_{SE}=2$ on average, as was observed in case of
512	null alleles (De Meeûs, 2018).
513	The proportion of locus pairs in significant LD varied between 8% and 53%
514	depending on the population structure and mating system (average 18%). With the
515	Benjamini and Yekutieli False Discovery Rate correction, this varied between 0% (majority
516	of cases) and 15% (average 3%). The effect of stuttering on LD was never significant,
517	whatever the mating system (all <i>p</i> -values>0.388). This could be expected since in our
518	simulations, stuttering was not correlated between loci. In real datasets, however, it may
519	occur that stuttering happen in samples with issues (poor preservation, mutations affecting
520	the zone of primers' anchorage, low DNA concentration). In that case, several loci of the
521	same individuals will be affected together, then producing fake significant LDs, as was
522	observed for the tick I. scapularis (De Meeûs et al., 2021).
523	
524	Generalized linear mixed models
525	The generalized linear mixed models confirmed the results seen above with more
526	accuracy.
527	For the number of significant tests, the results figure in Table 5. All parameters
528	appeared to display a significant effect that stayed so after BH correction. The most
529	important parameters were stuttering (positive effect), mating system (selfing increases the
530	effect) and their interaction (more effect of stuttering in random mating dioecious
531	populations). Number of subpopulations and subpopulation sizes displayed a rather weak
532	(though significant) negative effect, but this is probably an artefact due to inconsistencies
533	of results as a function of $n$ or $N$ (see supplementary File S1). For instance, $N=50$ , under
534	H0 with random mating, provided the smallest numbers of significant stuttering while
535	<i>N</i> =100 provided more significant results than <i>N</i> =200. In the same framework, for
536	subpopulation numbers, it was $n=500$ that provided the smallest number of significant
537	tests, followed by 100 and 50. Similar observations can be done for 10% of alleles affected
538	by stuttering and/or in monecious populations with 30% selfing (see supplementary File
539	S1).
540	

541	Table 5: Summary of the generalized linear mixed model for the number of loci found with
542	a significant stuttering (response variable) with the new alternative multi-
543	subsamples method. Explanatory variables were: $n$ (number of subpopulations), $N$
544	(subpopulation size), mating system (dioecious pangamy or monoecy with 30%
545	selfing) and stuttering intensity (0 or 10%). In case of qualitative variables (mating
546	system), the modalities with least positive effects are compared to the one with the
547	most positive effect (not shown in the output of the analysis). ":" stands for the
548	interaction between two variables. Coefficient estimates (Estimate), standard error
549	(SE), the Z statistic and its p-value are given.

	Estimate	SE	Ζ	<i>p</i> -value

For LD, results are presented in Table 6. The main effects were hold by *n*, with a 552 553 positive impact, and mating system with a strong negative impact of random mating as 554 compared to selfing. Subpopulation sizes seemed to play a weaker though significant role. 555 Nevertheless, the pattern of simulations explored introduced a strong collinearity between 556 n and N. If n is removed from the model, then N become highly significant with a much stronger (as expected) negative impact (Coefficient of estimate=-0.006). Stuttering did not 557 558 influence at all the occurrence of significant linkage disequilibrium between pairs of loci. 559 These conclusions did not change when the Benjamini and Hochberg, procedure was 560 applied to these series of *p*-values. 561

### 573 Clonal populations

574 The proportion of significant stuttering <u>detection</u> was very <u>large</u>, even under H0: 575 53% of significant tests, 50% with Benjamini and Hochberg, Under H1, these proportions 576 increased slightly (61 and 57.5 % respectively), but not significantly so (for the uncorrected \$77 tests, the Fisher exact test outputted a p-value=0.157). Wilcoxon rank sum tests found no 578 significant difference between data without stuttering and data with 10% stuttering for Fis 579 or RsE (p-value=0.2481 and p-value=0.4698, respectively). The expectation for Fis 580 following Balloux et al (2003)'s Equation 10 (Balloux et al., 2003), for an infinite allele 581 model, and set for full clonality, gives:  $F_{\rm IS} = \frac{\gamma[q_s - \gamma(q_s - q_d)]}{2N(1 - \gamma)[\gamma(q_s - q_d) - 1] - \gamma[q_s - \gamma(q_s - q_d)]}$ 582 583 with  $\gamma = (1-u)^2$ ;  $q_s = (1-m)^2 + m^2/(n-1)$ , and  $q_d = (1-q_d)/(n-1)$ . 584 With the actual parameters, this gave Fis\_exp=-0.3284. The averages of Fis and 95% 585 bootstrap confidence intervals (95%CI) were, Fis=-0.3649 in 95%CI=[-0.409, -0.315] 586 without stuttering; and Fis=-0.3443 in 95%CI=[-0.3962, -0.2845], with 10% stuttering. Both 587 confidence intervals largely overlapped and contained Fis exp.

- 588 <u>Clonal populations generated very high proportions of false stuttering detections</u>.
- 589 <u>This was because without segregation of alleles, only some classes of heterozygotes</u>

Supprimé: signatures

**Supprimé:** were consistent with this expectation:

Déplacé (insertion) [2]

596	propagate by chance. Heterozygote classes with one repeat difference are quite rare.
597	Indeed, if all 20 alleles were present (which never happened), there would be 19
598	heterozygote classes with one repeat difference amongst $\binom{20}{2}$ =190 possible heterozygous
599	states, hence a proportion of 0.1. Nevertheless, not all allele combinations were kept by
600	drift, which means that in many instances, even if some alleles were one repeat different at
601	the end of simulations, no such heterozygotes were kept by drift. This produced many
602	tests with very small p-values<0.0001, but also many with very high p-values>0.5: 43 %
603	and 53 % respectively. Put it another way, many simulations ended with no individuals
604	heterozygous for two alleles with one repeat difference, and many others with too many of
605	those (more than 20%): 40 % and 20 % respectively. This also explains why stuttering did
606	not have much impact on the global results, such as $F_{\rm IS}$ estimates. It means that much
607	more than 10% stuttering will be needed to significantly affect parameter estimates in
608	clonal organisms. In such situations, stuttering detection will need being considered with
609	the necessary prudence (see the conclusion) in fully clonal populations. In partial clones,
610	and given the lack of accuracy of the expected number of heterozygotes with one repeat
611	difference, using the panmictic expectations will probably display better performances.
612	
613	Cured data
614	$\ensuremath{\sc The}$ alleles that were indeed pooled are highlighted with the same color and can be
615	found in excel files that are contained in the supplementary file S3 (zipped file)
616	"PoolingProtocolCureSupFileS3.zip ".
617	In dioecious pangamic simulations, cured data did not entirely fix the stuttering
618	problem. Indeed, using the new method for stuttering detection, eight tests (1.3 %)
619	remained significant after BH correction, which is significantly more than the initial absence
620	of significant test (Fisher exact test, p-value=0.0076), before stuttering was introduced
621	(H0). In monoecious populations with 30% selfing, two tests remained significant (0.5 %),
622	which is not significantly more than the initial result (one significant test) under H0 (p-

623 value=1).

Regarding *F*<sub>is</sub> estimates, in pangamic simulations, the fit between the expected
values and the one observed in simulations under the null hypothesis, was not very good
and better for <u>larger</u> *n*'s (not shown). We thus preferred the more complex but more
accurate equation 11 in (Vitalis, 2002):

$$F_{\rm IS\_exp} = -\frac{\gamma[q_s - \gamma(q_s - q_d)]}{2N[1 - \gamma(q_s - q_d)] + \gamma[q_s - \gamma(q_s - q_d)]}$$

629 With this equation, the fit was very good, as can be seen in Figure 2.

19

Supprimé: tried out

**Commenté [FH11]:** I am not convinced, especially because partial but high clonal rate (above 0.9) would lead to a very twisted distribution of FIS values across loci (see for ex fig 3 in Stoeckel & Masson 2014).

**Supprimé:** The strategy used to pool close in size alleles followed what was written in the Material and Methods section.

Supprimé: bigger

644 estimates, driving it sometimes quite far above the expected value. Cured data, though

always providing values higher as compared to H0, always included the expected value intheir 95% confidence intervals.

647 As can be seen from Figure 3, in monoecious simulations with 30% of selfing, the fit 648 is almost perfect between  $F_{\text{IS}\_exp}$  and the value obtained under H0 (no stuttering).

649 Stuttering expectedly significantly increased observed Fis, while cured data presented

- 650 values that were almost superimposed with expected ones.
- 651

655

Figure 3: Comparison of Wright's *F*<sub>is</sub> estimates obtained in different simulations in monoecious populations with 30% selfing, without stuttering, with 10% stuttering and with 10% stuttering cured data. The *F*<sub>is\_exp</sub>=*s*/(2-*s*), is represented, as are the 95% bootstraps confidence intervals (Li and Ls) around observed values.

In conclusion, 10% stuttering significantly increased Fis and the cure used
reasonably restored the Fis expected under the null hypothesis, and particularly so in
inbred populations (with 30% of selfing).

661

# 662 Real datasets

For *I. scapularis* from Western USA, MicroChecker test only found <u>one locus with</u> significant stuttering out of <u>nine</u> (i.e. <u>11%</u>), <u>after exact binomial tests and Benjamini and</u> <u>Hochberg correction</u>. Alternatively, the new method developed here found three loci out of nine loci with a significant stuttering (33%), <u>Cured data provided results in agreement with</u> a pangamic reproductive strategy, as was already observed by the authors (De Meeûs et al., 2021).

For *Glossina palpalis palpalis* in Côte d'Ivoire, no binomial tests provided a
significant result with MicroChecker statistics. For the new method presented here, two loci
(B3 and XB110) out of seven (22.22%) displayed a significant stuttering, Cured data set
was obtained by pooling alleles following De Meeûs et al (2019)'s rules (De Meeûs et al.,
2021) (see Appendix 2, A2.1), This cure provided a slightly lower *F*<sub>is</sub>=0.221 (instead of
0.231) for locus B3, but a higher one for locus XB110 (*F*<sub>is</sub>=0.277 instead of 0.252),

Mis en forme : Police :Non Italique

#### Mis en forme : Police : Non Italique

Supprimé: , the results were similar between those obtained with our method and the published results with MicroChecker because these were submitted neither to exact binomial tests nor to subsequent BH correction. Nevertheless

Supprimé: the 171 that could be made

# Supprimé: 4.09

**Supprimé:** After exact binomial tests, only a single locus gave a significant stuttering test with MicroChecker (11%). All these tests stayed significant after BH correction

**Supprimé:** , no stuttering was initially found because author used a different criterion (a significant global heterozygote deficit was necessary to validate a onerepeat heterozygote deficit observed in the graphics of MicroChecker) as compared to what we used here. Nevertheless, only two tests out of 98 (2.04%) gave a significant stuttering with MicroChecker, and

### Supprimé: , even after BH correction

Déplacé vers le bas [1]: For Locus B3 allele 203 was recoded 201; allele 207 was recoded 205; allele 211 was recoded 209; and alleles 215 was recoded 213. For Locus XB110, alleles 179 was recoded 177; allele 183, was recoded 181; alleles 187 to 199 were recoded 185, allele 203 was recoded 201 and all rare alleles from 205 to 277 were also recoded 203.

703	meaning that the heterozygote deficit at this locus was better explained by another
704	phenomenon (i.e. null alleles).
705	In G. truncatula, after Benjamini and Hochberg correction, 50% of loci displayed a
706	significant stuttering, while all six loci were significant with the new method (all p-
707	BH<0.0104). Allele pooling for curing the data was as described in Appendix 2 (A2.2), This
708	cure lowered the $F_{\rm IS}$ for three loci, Lt9 (0.778 to 0.776), Lt16 (0.958 to 0.006), and Lt24
709	(0.966 to 0.947) and increased it for the others. However, missing data (assumed null
710	homozygotes) explained almost 50% of Fis variation, with a highly significant Spearman's
711	rank correlation between $F_{IS}$ and number of blank genotypes ( $p$ =0.9411, $p$ -value=0.0025),
712	while with the data set cured for loci Lt9, Lt16 and Lt24, the correlation dropped to a non-
713	significant value (p-value=0.2589). When removing the correction for locus Lt16, which
714	provided an outlier as compared to other loci, the correlation became significant again (p-
715	value=0.0103), but with a smaller correlation ( $ ho$ =0.8804) and only 41% of $F_{\rm IS}$ variation
716	explained by missing genotypes.
717	For F. hepatica, no locus was significant with MicroChecker, while only one locus
718	(Fh28) presented a significant stuttering signature after Benjamini and Hochberg
719	correction (p-BH=0.0001). Pooling of alleles at this locus is described in Appendix 2
720	(A2.3), The Fis of cured data dropped from 0.644 to 0.536. However, we knew that null
721	alleles explained well most of the observed heterozygote deficit (Correa et al., 2017), and
722	the correlation between missing data and $F_{\rm IS}$ , when excluding one locus (Fh25) that
723	displayed too many missing genotypes, was initially significant ( $\rho$ =1, $p$ -value=0.0417), with
724	83 % of the $F_{\rm IS}$ variation explained by blank genotypes. In the cured data, it dropped to a
725	not significant relationship ( $p$ =0.8, $p$ -value=0.1667), with 72 % of $F_{\rm IS}$ variation explained by
726	missing genotypes.
727	These discrepancies strongly suggested that stuttering detection in <i>G. truncatula</i>
728	and F. hepatica corresponded to type error I, due to the fact that null alleles better explain
729	the data and probably interacted with our stuttering detection test. It shows that several
730	checks need being undertaken before deciding that a locus is significantly affected by
731	stuttering and requires being cured, especially in selfing species.
732	For the clonal <i>T. brucei gambiense</i> 1, we avoided using MicoChecker (for obvious
733	reasons). With the method expounded in the present paper, three loci displayed a
734	significant stuttering signature; micbg1, misatg4 and misatg9. These loci were cured as in
735	Appendix 2 (A2.4), These loci presented a lower Fis when cured: from -0.647 to -818, from
736	-0.579 to -0.72, and from -0.471 to -0.496 for micbg1, misatg4 and misatg9, respectively.
737	Moreover, several observations suggested an improvement of the guality of the data after

761 the cure for stuttering. The proportion of significant linkage disequilibrium between locus 762 pairs increased from 53% (uncured data) to 80% (data cured for the three loci), and the 763 superimposition S<sub>C</sub> increased from 0.9554 to 0.9782, from 0.9800 to 0.9975, and from 764 0.9539 to 0.9663 for micbg1, misatg4 and lisatg9 respectively, Three loci with missing 765 genotypes could be suspected to display null alleles, i.e. misatg4, misatg9 and m6c8. 766 When these loci were removed, averaged superimposition increased to Sc=0.9908. Here 767 again, we can see that some checks allowed deciding that stuttering corrections were valid 768 and significantly improved the quality of the data. After stuttering cure, removing other loci 769 with suspected null alleles (i.e. with missing genotypes) drove the superimposition index 770 defined in the Material and Methods section to almost unity, i.e. a perfect fit with the expected value under full clonality known to occut in that species (Weir et al., 2016). 771 772

### 773 <u>Conclusions</u>

777

778

The new method developed here appeared at least three times more efficient (and
 often much more) than MicroChecker, <u>Moreover</u>, the use of spreadsheet programs makes
 its portability universal for any microcomputer.

In dioecious pangamic populations, like ticks and tsetse flies, detection works well and cure improves population genetics parameter estimates but not perfectly so, which means that, for instance,  $F_{IS}$  and  $F_{ST}$  will still be slightly overestimated in datasets cured for stuttering. So, whenever possible, removal of affected loci may help to shift such estimates towards (slightly) more accurate values.

In monoecious selfers, detection works well and cure works very well, providing other confounding factors as null alleles do not interfere, in which case avoiding stuttering cure and correct for null alleles appear more appropriate. In doubt, and for subdivision measures, curing for null alleles may be achieved by the elimination of involved loci for strong selfers, or applying the INA correction (Chapuis & Estoup, 2007), for reasonably panmictic populations.

In clones, only highly significant stuttering tests with a significant higher *F*<sub>IS</sub> as
compared to other loci, will need being cured, in which case parameter estimates may be
<u>much</u> improved.

In any way, cure must only be kept if *F*is values are improved (lower than it wasinitially) and special care must be devoted to the behavior of their variation in relation to

 $\ensuremath{\textit{Supprimé:}}$  . The average for cured data was then  $S_{\text{C}} {=} 0.9718,$  which is very important

### Supprimé: Discussion

Supprimé: The power of stuttering detection was weak, except in populations with an increased inbreeding coming from a closed system of mating. In this case, BH correction allowed reducing the false discovery rate to a reasonable level.¶

**Supprimé:** Selfing significantly increased power detection as discussed above.

Supprimé: The stuttering proportion used here was relatively small, since the realized actual proportion of alleles affected at the end of simulations was in general much lower on average. Indeed, in many subsamples, the two first consecutive allele chosen for stuttering must be present and preceded or followed by an allele with one repeat difference. Otherwise, no stuttering occurs. Nevertheless, this was enough to generate significant heterozygote deficits under the pangamic dioecious mating system. Alternatively, this may also explain why stuttering had no significant impact on the *F*<sub>IS</sub> of monoecious selfers. Nevertheless, stuttering detection significantly increased with local inbreeding.

Stuttering had a quite small impact on the ratio between the standard error of  $F_{IS}$  and  $F_{ST}$ , which did not reach the minimum two-fold threshold met with null alleles (De Meeûs, 2018)

Supprimé: Stuttering did not affect linkage disequilibrium. This might have been expected here since how stuttering was generated did not affect more any individual than another. In real life, we may expect amplification problems to affect preferentially some individuals, at several loci, due to several possible and nonexclusive reasons: bad preservation of several DNA extracts, genetically distant individuals (genetically distant populations, subspecies, or cryptic species), and bad amplification conditions. In that case, we may expect some correlation between the affected loci thus generating an increase in linkage disequilibrium between those, as this appeared to be the case for the tick *I. scapularis* in USA (De Meeûs et al., 2021).¶

Subpopulation sizes and number of subpopulations did not affect much stuttering discovery. There is indeed no reason why the effect of stuttering would be increased or decreased by those parameters. The lim

Déplacé vers le haut [2]: Clonal populations generated very high proportions of false stuttering detections. This was because without segregation of alleles, only some classes of heterozygotes propagate

Supprimé: The strategy to cure the data suffering from stuttering did not allow to entirely restore a completely immune set of population genetics results in pangamic dioecious populations, though the 95%

Déplacé vers le haut [3]: After this cure, removing other loci with suspected null alleles (i.e. with missing genotypes) drove the superimposition index defined in

1114	Appendices
1115	Appendix 1: R-scripts and R-commander menu used to analyse the different
1116	datasets
1117	Regarding R-scripts, most are very small and basic: binom.test, for the exact binomial
1118	test; p.adjust, for adjusting the p-values in a series of p-values.
1119	
1120	For generalized linear mixed models with the package Ime4, the commands were, for the
1121	number of significant stuttering tests (for instance):
1122	
1123	Dataset <-
1124	read.table("C:/DeMeeus/thierry/StutteringTest/DataMixedModelStutterSimul.txt",he
1125	ader=TRUE)
1126 1127	<pre>SigStutl&lt;-glmer(StutterSigSperLocus~n+N+Mating+Stuttering+(1 Rep), family=poisson(link = "log")</pre>
1128	summary(SigStut1)
1129	
1130	
1131	The Fisher exact tests were undertaken with R-commander, in the menu Statistics-
1132	Contingency table-Enter and analyze two-way table
1133	
1134	
1135	Appendix 2: Pooling of alleles used to cure real datasets
1136	A2.1. For Ixodes scapularis
1137	For Locus B3 allele 203 was recoded 201; allele 207 was recoded 205; allele 211
1138	was recoded 209; and alleles 215 was recoded 213. For Locus XB110, alleles 179 was
1139	recoded 177; allele 183, was recoded 181; alleles 187 to 199 were recoded 185, allele 203
1140	was recoded 201 and all rare alleles from 205 to 277 were also recoded 203.
1141	
1142	A2.2. For Galba truncatula
1143	For locus Lt9, 203 with 202, 210 and 212 with 208; for Lt16, 231 to 233 with 230; for
1144	Lt21, 107 with 105, 112 with 111, 115 and 116 with 114; for Lt24, 208 and 210 with 207.
1145	215 to 217 with 214, 220 and 221 with 219: for Lt36, 187 to 190 and 192 with 185: and for
1146	1 t37, 115 with 113, and 123 with 212.
1147	
1148	A2.3. For Fasciola hepatica
1149	Alleles 182 to 183 with 180, allele 188 with 186, and alleles 192 to 194 with 190
.   .0	29

- 1151 A2.4. For Trypanosoma brucei gambiense 1
- 1152 1153 1154 for micbg1, allele 164 was pooled with 162, and allele 194 with 192; for misatg4, allele 117
- with 115, and 145 with 143; and for misatg9, alleles 130 and 128 with 126, allele 186 with
- 184, and alleles 194 and 192 with 190.
